The stochastic nature of ecological interactions has led biologists to adopt a probabilistic view of ecological networks. Representing species interactions probabilistically (how likely are they occurring?) as opposed to deterministically (are they occurring?) allows a better assessment of their spatiotemporal variability and accounts for inherent uncertainties in both observations and predictions. However, despite this growing interest in probabilistic networks, guidelines for the estimation and documentation of probabilistic interaction data are still lacking. This is concerning given that our biological understanding of probabilistic interactions and their appropriate analyses depend on the often elusive methods and variables used for their estimation. We review how probabilistic interactions are defined at different spatial scales, from local interactions to regional networks (metawebs), with a strong emphasis on trophic interactions. These definitions are based on the distinction between the observation of an interaction at a specific time and space and its biological feasibility. We show that different network representations have different statistical properties when it comes to common ecological applications. Specifically, we argue that local probabilistic networks and metawebs differ in their spatial and temporal scaling of interactions, with potential interactions in metawebs remaining constant across spatial and temporal scales. This is in contrast with the taxonomic scaling of interactions, which does not qualitatively differ between both types of networks. We suggest two approaches to inferring deterministic networks from probabilistic webs that account for these differences and argue that systematic biases arise when directly inferring local networks from subsets of metawebs. To support our arguments, we build a spatiotemporally explicit model of probabilistic interactions and develop different case studies using empirical data on host-parasite interactions in Europe. Overall, our results underscore the importance of clear metadata for probabilistic ecological networks, both at the local and regional scales, to inform the appropriate reuse of interaction data.

1 Introduction

2 Cataloging ecological interactions is a substantial challenge. There are methodological and biological
3 constraints that hinder our ability to observe all interactions, such as the spatial and temporal uncoupling of
4 species (Jordano (1987)) and the large number of possible interactions in a community, of which the vast
5 majority are rare (Jordano (2016)). Documenting the location and timing of interactions becomes even more
6 difficult when accounting for the spatiotemporal variability of ecological networks (Poisot *et al.* (2012), Poisot
7 *et al.* (2015)). Indeed, knowing the biological capacity of two species to interact is necessary but not sufficient
8 for inferring their interaction at a specific time and space. For example, Golubski & Abrams (2011) presented
9 many cases where trophic interactions in food webs depend on the presence or abundance of a third species
10 (e.g., of a more profitable prey species). More generally, a handful of conditions must be satisfied for an
11 interaction to be observed locally. First, both species must have overlapping geographic ranges, i.e. they must
12 co-occur within the region of interest (Blanchet *et al.* (2020)). Then, they must encounter locally. Probabilities
13 of interspecific encounters are typically low, especially for rare species with low relative abundances (Canard *et*
14 *al.* (2012)). Finally, their traits must be locally compatible (Poisot *et al.* (2015)). This includes their phenology
15 (Olesen *et al.* (2010), Singer & McBride (2012)), behavioral choices (Pulliam (1974), Choh *et al.* (2012)) and
16 phenotypes (Bolnick *et al.* (2011), Stouffer *et al.* (2011), Gravel *et al.* (2013)). Environmental factors, such as
17 temperature (Angilletta *et al.* (2004)), drought (Woodward *et al.* (2012)), climate change (Gilman *et al.* (2010),
18 Woodward *et al.* (2010), Araujo *et al.* (2011)), and habitat modifications (Tylianakis *et al.* (2007)), contribute
19 to this spatiotemporal variability of interactions by impacting species abundance and traits. In this context, it is
20 unsurprising that our knowledge of ecological interactions remains limited (Hortal *et al.* (2015)) despite
21 extensive biodiversity data collection (Schmeller *et al.* (2015)).

22 The recognition of the intrinsic variability of species interactions has led ecologists to expand their
23 representation of ecological networks to include a probabilistic view of interactions (Poisot *et al.* (2016)). As
24 opposed to binary deterministic networks, in which interactions are regarded as either occurring or not,
25 probabilistic networks represent our degree of belief about the realization or feasibility of pairwise interactions
26 at the local or regional scale, respectively. In other words, representing interactions probabilistically takes into
27 account inherent uncertainties and variability associated with ecological data. In the broadest sense, binary
28 networks are also a type of probabilistic network, in which the numerical value of an interaction is restrained to
29 0 (non-occurring) or 1 (occurring). In probabilistic networks, only forbidden interactions (i.e., interactions

prohibited by biological traits, Jordano *et al.* (2003), Olesen *et al.* (2010)) have a probability value of zero, provided that intraspecific trait variability is considered (Gonzalez-Varo & Traveset (2016)). However, *neutrally* forbidden interactions (i.e., improbable interactions between rare species, Canard *et al.* (2012)) could have low probability values in local networks but high probability in a regional network (metaweb) describing the biological capacity of species to interact.

By accounting for the uncertainty of interactions, probabilistic networks provide a more realistic portrait of species interactions and network structure (i.e. community-level properties), which is a major driver of the functioning, dynamics, and resilience of ecosystems worldwide (Proulx *et al.* (2005), McCann (2007), McCann (2011), Rooney & McCann (2012)). Moreover, the application and development of computational methods in network ecology, often based on a probabilistic representation of interactions, can alleviate the sampling efforts required to document species interactions (Strydom *et al.* (2021)). For example, statistical models can be used to estimate the uncertainty of pairwise interactions (Cirtwill *et al.* (2019)) and the probability of missing (false negatives) and spurious (false positives) interactions (Guimerà & Sales-Pardo (2009)). Considering the high rate of false negatives in species interaction data due to the difficulty of witnessing rare interactions (Catchen *et al.* (2023)), these models could inform the identification of priority sampling locations of ecological networks where data collection would yield the most valuable information, thereby reducing errors. Optimization models for sampling locations have mostly found applications in biological systems that are not networked, such as identifying priority sampling sites for disease hotspots (Andrade-Pacheco *et al.* (2020)), but there is substantial promise in applying them to probabilistic ecological interactions. Statistical models can also be used to generate network predictions without prior knowledge of pairwise interactions, for instance using body size (Petchey *et al.* (2008), Gravel *et al.* (2013)), phylogeny (Elmasri *et al.* (2020), Strydom *et al.* (2022)), or a combination of niche and neutral processes (Bartomeus *et al.* (2016), Pomeranz *et al.* (2019)) for inference. Topological null models (e.g., Bascompte *et al.* (2003), Fortuna & Bascompte (2006)), which can be used to generate underlying distributions of network measures for null hypothesis significance testing, are other examples of common probabilistic network models. Many measures have been developed to describe the structure (Poisot *et al.* (2016)) and diversity (Ohlmann *et al.* (2019), Godsoe *et al.* (2022)) of probabilistic networks. These models and measures support the use of this approach for the study of a wide range of ecological questions, from making better predictions of species distribution (Cazelles *et al.* (2016)) to forecasting the impact of climate change on ecological networks (Gilman *et al.* (2010)).

The lack of clear guidelines on the use of probabilistic interaction data is worrisome (Brimacombe *et al.*

60 (2023)), both for data producers and re-users who generate and manipulate these numbers. Besides
61 methodological difficulties that may arise when assessing probabilistic interactions, a precise definition of
62 probabilistic interactions appears to be lacking, making the estimation and use of these data more difficult. We
63 aim to take a step back by outlining different ways in which probabilistic interactions are defined and used in
64 network ecology. We distinguish two broad categories of probabilistic networks that necessitate distinct
65 approaches when applied to key ecological questions: local networks of realized interactions, and regional
66 networks (metawebs) of potential interactions. We highlight the distinctions in the ecological meaning of these
67 two representations and show that they yield different statistical outcomes regarding e.g. the spatial and
68 temporal scaling of interactions and the prediction of binary networks across space. Moreover, there is currently
69 no metadata standard that could guide the documentation of all types of probabilistic interactions (Salim *et al.*
70 (2022) discuss data standards for deterministic mutualistic networks). Well-defined metadata for probabilistic
71 networks would support more adequate manipulation and integration of interaction data from different sources
72 and guard against the potential misinterpretations arising from ambiguous definitions of probabilistic networks.
73 These metadata should outline the nature (i.e., potential or local) and type (e.g., predatory or pollination) of the
74 interactions, provide information regarding the taxonomic level, identities, and characteristics (e.g., life stages)
75 of the individuals involved in an interaction, present the mathematical formulation of probabilities, including
76 clearly identified conditional variables, and describe the methods and contexts (e.g., location, time,
77 environmental conditions) in which interactions were estimated. Inadequately documented probabilistic
78 interaction data should be used with caution when analyzing ecological networks. Although our contribution
79 focuses on food webs, our observations and advice can be applied to other types of ecological networks, from
80 plant-pollinator to host-virus networks. Indeed, excluding networks of indirect interactions such as competition
81 and facilitation networks (Kéfi *et al.* (2015), Kéfi *et al.* (2016)), most ecological networks describe probabilities
82 of direct interactions, which are conceptually and mathematically analogous regardless of their biological type
83 (e.g., trophic and mutualistic interactions).

84 **Probabilistic representations of interactions**

85 One of the first aspects to take into consideration when estimating or interpreting probabilities of interactions is
86 knowing if they describe potential or realized interactions. A potential interaction is defined as the biological
87 capacity of two taxa to interact (i.e., the probability that they *can* theoretically interact) whereas a realized

interaction is the materialization or observation of this interaction in a well-defined space and time (i.e., the probability that they interact locally). Here, we use the terms *metaweb* (Dunne (2006)) to designate networks of potential interactions and *local networks* (Poisot *et al.* (2012)) for those of realized interactions. Metawebs are the network analogues of the species pool, where local networks originate from a subset of both species (nodes) and interactions (edges) of the regional metaweb (Saravia *et al.* (2022)). Without clear documentation, it can be challenging to know if published probabilistic networks describe potential or realized interactions, or if so-called probabilities are in reality *interaction scores* (i.e., non-probabilistic quantitative interactions). When probabilistic potential interactions are used and interpreted as local interactions (and conversely), this may generate misleading findings during data analysis. We believe that a better understanding of the differences, similarities, and relationships between these two probabilistic representations of ecological networks would alleviate interpretation errors and facilitate a more adequate utilization of interaction data.

99 Pairwise interactions: the building blocks of ecological networks

Local ecological networks and metawebs, like any type of network, are made of nodes and edges that can be represented at different levels of organization and precision. The basic unit of food webs and other ecological networks are individuals that interact with each other (e.g., by predation, Elton (2001)), forming individual-based networks (Melián *et al.* (2011)). The aggregation of these individuals into more or less homogeneous groups (e.g., populations, species, trophic species, families) allows us to represent nodes at broader taxonomic scales, which affects our interpretation of the properties of these systems (Guimarães (2020)). Moreover, edges linking these nodes can describe a variety of interaction measures. Ecologists have traditionally represented interactions as binary objects that were considered realized after observing at least one individual from group i interact with at least another individual from group j . Boolean interactions can be viewed as the result of a Bernoulli process $A_{i,j} \sim \text{Bernoulli}(P(i \rightarrow j))$, with $P(i \rightarrow j)$ being the probability of interaction between i and j that characterizes our limited knowledge of the system and its intrinsic spatiotemporal variability. Depending on the type of networks (local or metaweb), the mathematical formulation and interpretation of stochastic parameters like $P(i \rightarrow j)$ can be linked to environmental and biological factors such as species relative abundance, traits, area, and time (tbl. 1), for example using logistic regression with a logit link function with continuous explanatory variables. In these probabilistic network representations in which $P(i \rightarrow j)$ are edge values, the only two possible outcomes are the presence ($A_{i,j} = 1$) or absence ($A_{i,j} = 0$) of an interaction between each pair of nodes. When considering uncertainties around the

117 estimation of $P(i \rightarrow j)$, a Beta distribution $\text{Beta}(\alpha, \beta)$ can also be used to encompass all possible probability
118 values. Observing an interaction between two taxa at a given location and time provides important information
119 that can be used to update previous estimates of $P(i \rightarrow j)$, informing us on the biological capacity of both taxa
120 to interact and the environmental conditions that enabled them to interact locally.

121 Even though binary networks constitute a highly valuable source of ecological information (Pascual *et al.*
122 (2006)), they overlook important factors regarding interaction strengths. These are represented using
123 quantitative interactions, which better describe the energy flows, demographic impacts or frequencies of
124 interactions between nodes (Berlow *et al.* (2004), Borrett & Scharler (2019)), with $A_{i,j}$ being a natural number
125 \mathbb{N} or a real number \mathbb{R} depending on the measure. For example, they may represent local interaction rates
126 between pairs of taxa (e.g., the flower visiting rates of pollinators in a mutualistic network, Herrera (1989)).
127 Because quantitative interactions can also describe predation pressure on prey taxa in food webs, they can be
128 good estimators of the parameters describing species interactions in a Lotka-Volterra model (e.g., Emmerson &
129 Raffaelli (2004)). The extra amount of ecological information in quantitative networks typically comes at a cost
130 of greater sampling effort and data volume in predictive models (Strydom *et al.* (2021)), which can lead to
131 relatively high levels of uncertainties when inferring quantitative networks with limited data. Just like binary
132 networks, the uncertainty and spatiotemporal variability of quantitative interactions can be represented
133 probabilistically. However, the need to estimate the probability distribution of all possible value of interaction
134 strengths can make the inference of probabilities more challenging in quantitative networks compared to binary
135 networks, which require only one probability estimate for each interaction. Quantitative interactions can follow
136 various probability distributions depending on the measure used, the event's outcome being the value of
137 interaction strength. For instance, quantitative interactions can follow a Poisson distribution
138 $A_{i,j} \sim \text{Poisson}(\lambda_{i \rightarrow j})$ when predicting frequencies of interactions between pairs of nodes, with $\lambda_{i \rightarrow j}$ being the
139 expected rate at which individuals of taxa i and j interact (e.g., the average number of prey j consumed by all
140 predators i in a given time period). The Poisson distribution can also be 0-inflated after initially modeling
141 non-interacting taxa (e.g., Boulangeat *et al.* (2012) employ a 0-inflated model to analyze species abundance
142 following the modeling of species presence and absence), which constitute the majority of taxa pairs in most
143 local networks due to their typically high sparseness (Jordano (2016)). Because of the methodological
144 difficulties typically encountered when building deterministic quantitative networks, binary networks, which are
145 easier to sample (Jordano (2016)) and predict (Strydom *et al.* (2021)), are much more documented and modeled
146 in the literature. Moreover, most published probabilistic networks and methods describe Bernoulli interactions

147 (whether interaction probabilities are regarded as constant or variable, e.g. represented by Beta distributions),
148 which underlines the need for better guidelines regarding the interpretation and manipulation of these types of
149 networks. For these reasons, our primary focus in this contribution will be on addressing the challenges in
150 interpreting and using Bernoulli interactions, in both probabilistic local networks and metawebs.

151 **Local networks: communities interacting in space and time**

152 Probabilistic local networks describe how likely taxa are to interact at a given location and time period (i.e.,
153 interactions are contingent upon the environmental and biological conditions of the community). In local
154 networks, edges commonly represent our degree of belief that two taxa interact in nature, but can also represent
155 the probability of *observing* this interaction (Catchen *et al.* (2023)). For example, Kopelke *et al.* (2017)
156 assembled a dataset of binary local European food webs of willow-galling sawflies and their natural enemies,
157 clearly referencing each food web in space and time. Gravel *et al.* (2019) used this dataset to infer the
158 probabilities of locally observing interactions between co-occurring species, with the added aspect of situating
159 local networks within the context of environmental variables. This was achieved by including temperature and
160 precipitation as conditional variables in some of their models.

161 We define space as the set of geographic coordinates (x, y, z) of the spatial boundaries delineating the system,
162 whether sampled or targeted. Ecological interactions may exhibit variations spatially and along altitudinal
163 gradients, as evidenced by changes in hummingbird-plant interactions (Weinstein & Graham (2017b) and
164 Weinstein & Graham (2017a)) and mosquitoes biting rates (e.g., Kulkarni *et al.* (2006)) at different elevations.
165 In contrast, time is defined as the specific time period within which interactions were either observed or
166 predicted. With these definitions in mind, space and time can be conceptualized as distinct patches or time
167 segments. Treating them as discrete dimensions aligns with the common sampling methods of ecological
168 networks and provides actual probabilities of interactions across space and time. This differs from the approach
169 of treating them as continuous variables, where edge values represent probability densities (i.e., relative
170 likelihoods of interactions occurring at infinitesimal locations and instants in time) rather than discrete
171 probability values (which can be obtained by integrating probability densities). By employing discrete locations
172 and time periods, we can quantify both an area A and a duration t , which can be readily used in spatiotemporal
173 analyses of ecological networks. For example, when studying network-area relationships (NAR, Galiana *et al.*
174 (2018)), we anticipate that local probabilities of interactions scale positively with area and duration because
175 taxa have more opportunities to interact as these dimensions expand.

176 The probability that two taxa i and j interact locally can be conditional on many environmental and biological
 177 factors. One of these is their co-occurrence $C_{i,j}$, which is usually a Boolean describing if the geographic
 178 distributions of both taxa overlap within the study area. Co-occurrence can be modeled probabilistically, in
 179 which case it may conform to a Bernoulli distribution $C_{i,j} \sim \text{Bernoulli}(P_{i,j}(x, y, z))$, where the probability of
 180 co-occurrence $P_{i,j}(x, y, z)$ can be estimated through the application of joint species distribution models (e.g.,
 181 Pollock *et al.* (2014)). Considering that the probability that two non co-occurring taxa interact locally is zero
 182 (i.e., $P_N(i \rightarrow j|C = 0) = 0$), the probability of local interaction can be obtained by multiplying the probability of
 183 interaction given co-occurrence with the probability of co-occurrence:

$$P_N(i \rightarrow j) = P_N(i \rightarrow j|C = 1) \times P_{i,j}(x, y, z). \quad (1)$$

184 Other important factors that can impact our estimation of interaction probabilities at the local scale are taxa
 185 relative abundance (Canard *et al.* (2012)) and traits (Poisot *et al.* (2015)), as well as environmental factors such
 186 as temperature (Angilletta *et al.* (2004)), precipitation (Woodward *et al.* (2012)), habitat structure (Klecka &
 187 Boukal (2014)), and presence of other interacting taxa in the network (Pilosof *et al.* (2017), Kéfi *et al.* (2012)).
 188 Here, we use the variable Ω to describe the biological and ecological context in which interaction probabilities
 189 were estimated. For example, if a research team conducts a mesocosm experiment to estimate interaction
 190 probabilities between predators and prey with and without shelters, Ω would represent the presence or absence
 191 of these shelters. Like co-occurrence, Ω can also be modeled probabilistically when the stochasticity or
 192 uncertainty of environmental and biological factors is considered. In sum, Ω represents all ecological and
 193 biological variables that were taken into consideration when measuring interaction probabilities and is,
 194 therefore, a subset of all factors actually impacting ecological interactions.

195 The probability that two taxa i and j interact in a local network N can thus be conditional on the area A , the time
 196 interval t , their co-occurrence C and chosen environmental and biological conditions Ω . This gives us the
 197 following equation when all of these conditions are included in the estimation of interaction probabilities:

$$P_N(i \rightarrow j|A, t, C, \Omega). \quad (2)$$

198 The representation of the local context in which probabilities are estimated and the variables that should be
 199 taken into consideration depend on the study system, the objectives of the study, and the resources available to

200 the researchers. In other words, these variables do not systematically need to be accounted for. For example, in
 201 Gravel *et al.* (2019), for the purpose of model comparison, some models incorporated environmental variables
 202 as conditional factors to estimate interaction probabilities, while others did not. When accounted for, these
 203 variables should be clearly described in the documentation of the data (Brimacombe *et al.* (2023)),
 204 preferentially in mathematical terms to avoid any confusion in their interpretation and to limit manipulation
 205 errors during their re-use. For instance, ecologists should be explicit about their consideration of co-occurrence
 206 in their estimation of local interaction probabilities. Indeed, it is important to specify if probability values are
 207 conditional $P_N(i \rightarrow j|C = 1)$ or not $P_N(i \rightarrow j)$ on co-occurrence since this can significantly impact the
 208 interpretation and analysis of the data. In [tbl. 1](#), we present a handful of studies of probabilistic networks that
 209 used diverse formulations of probabilistic interactions, highlighting the importance of a thorough description of
 210 interaction data.

Table 1: Notation and description of probabilistic interactions. The probability of interaction between two taxa i and j is interpreted differently in a metaweb M and local network N . Each formula includes a different conditional variable described in plain text. A non-exhaustive list of studies using these conditional variables is included, with the variables used specified in parentheses. Note that interaction probabilities can be contingent upon multiple conditional variables, or none at all. Additionally, local interaction probabilities might represent the probability of observing an interaction, not necessarily its actual occurrence.

Formula	Type	Definition	Studies
$P_M(i \rightarrow j)$	potential	biological feasibility of the interaction	
$P_N(i \rightarrow j)$	local	realization of the interaction at any given location and time	
$P_N(i \rightarrow j A)$	local	realization of the interaction in a given area	
$P_N(i \rightarrow j t)$	local	realization of the interaction during a given time period	
$P_N(i \rightarrow j C)$	local	realization of the interaction given that the taxa co-occur	
$P_N(i \rightarrow j \Omega)$	local	realization of the interaction given environmental and biological conditions	

211 **Metawebs: regional catalogs of interactions**

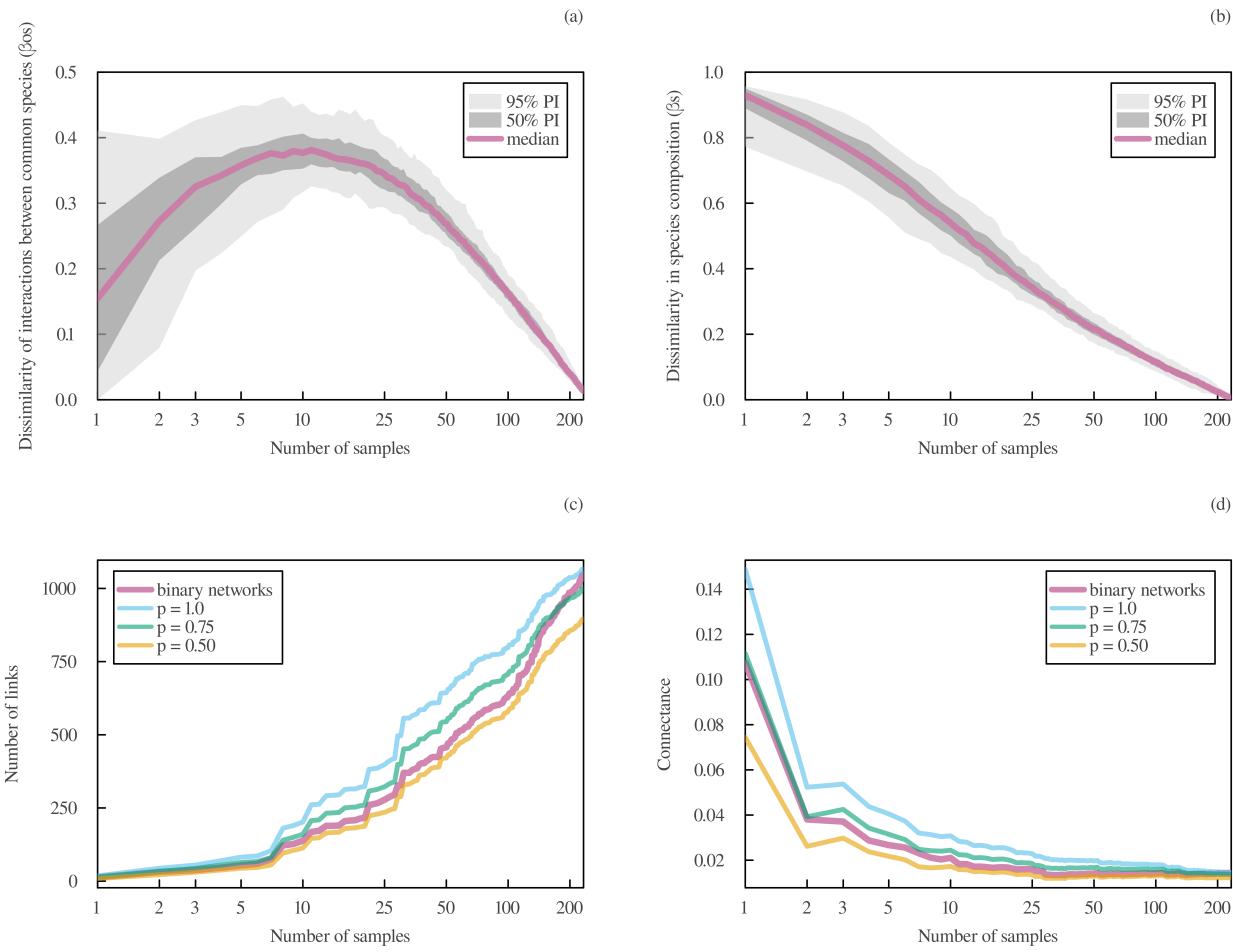

212 Metawebs are networks of potential interactions that have been designed for broad spatial, temporal, and
213 taxonomic scales (e.g., species food webs at the continental scale). They represent the probability that two taxa
214 can biologically interact regardless of their co-occurrence and local environmental conditions. Potential
215 interactions are by definition context-independent, i.e. they are not measured at a specific location and time. In
216 contrast with probabilistic local networks, which represent the stochasticity of interactions occurring in nature,
217 probabilistic metawebs measure our degree of belief in the capacity of two taxa to interact (i.e., the probability
218 that their traits could support an interaction in the right conditions). In other words, potential interactions
219 describe the probability that there exists at least one combination of phenotypes of taxa i and j that can interact
220 with each other if they were to encounter. This probability of interaction, in a metaweb M , can be expressed as

$$P_M(i \rightarrow j), \quad (3)$$

221 which, in contrast with eq. 2, is not conditional on any spatial, temporal, or environmental variables (tbl. 1).
222 Starting from a selected set of taxa, which are usually distributed within a broad region of interest, metawebs
223 can be built using different data sources, including literature review, fieldwork, and predictive models (e.g., the
224 metaweb of trophic interactions between Canadian mammals inferred by Strydom *et al.* (2022)). Every pair of
225 taxa that have confidently been observed to interact at least once can be given a probability of 1 (i.e.,
226 $P_M(i \rightarrow j) = 1$) since we know that they *can* interact. This is usually not the case in local probabilistic networks,
227 in which probabilities usually remain stochastic (i.e., $P_N(i \rightarrow j) < 1$) after empirically observing interactions
228 because of their intrinsic spatiotemporal variability. Similarly, although rare interactions typically have low
229 probabilities in local networks, they can have high probabilities in metawebs if the traits of both taxa match. On
230 the other hand, interactions that were never observed can have low probability values in both metawebs and
231 local networks, going as low as 0 for forbidden links. However, because of observation errors due to taxonomic
232 misidentifications and ecological misinterpretations (e.g., due to cryptic species and interactions, Pringle &
233 Hutchinson (2020)), many observations of interactions are only false positives. Similarly, forbidden interactions
234 can be false negatives in metawebs, e.g. if they have been assessed for specific phenotypes, locations or time.
235 Implementing a Bayesian framework, which updates prior probabilities with empirical data (e.g., Bartomeus *et*
236 *al.* (2016), Cirtwill *et al.* (2019)), could improve our estimation of interaction probabilities in both systems.

237 Probabilistic networks in action

238 The differences in the mathematical formulations of local and potential interactions can affect their statistical
239 properties when applied to key ecological questions. These disparities must therefore be taken into account
240 when analyzing probabilistic interaction data to prevent misleading results and minimize interpretation errors.
241 Here we show four common applications of probabilistic interactions and compare the characteristics of local
242 networks and metawebs using simulated and empirical data.

243

244 Taxonomic scaling of interactions

245 Probabilistic networks can be used to address a wide range of ecological questions based on their level of
246 organization. For example, the assemblage of interactions across ecological scales can be studied using
247 species-based networks, whereas clade-based networks can be used to study macroevolutionary processes (e.g.,
248 Gomez *et al.* (2010)). Because our interpretation of the properties and dynamics of ecological networks

depends on their taxonomic scale (Guimarães (2020)), examining the phylogenetic scaling of network structure is also a promising research avenue. Analyzing the same system at different taxonomic scales can thus provide meaningful and complementary ecological information and is, in our perspective, best conducted using probabilistic networks.

There is no qualitative difference in the taxonomic scaling of local networks compared to metawebs because only the nodes are defined taxonomically. In other words, the edge probability values of local networks (eq. 2) and metawebs (eq. 3) are not conditional on any taxonomic scale. It is the definition of the event itself (i.e., the interaction of the two taxa) that has a given phylogenetic scale, not their conditional variables. In both types of networks, shifting to a broader level of organization can be directly done using probabilities at finer scales. For example, if we have a network of n_A species from genus A and n_B species from genus B, we can calculate the probability that at least one species from genus A interact with at least one species from genus B as follows:

$$P(A \rightarrow B) = 1 - \prod_{i=1}^{n_A} \prod_{j=1}^{n_B} (1 - P(A_i \rightarrow B_j)), \quad (4)$$

where A_i and B_j are the species of the corresponding genus. Knowing that two species interact (i.e., $P(A_i \rightarrow B_j) = 1$) gives a probability of genus interaction of 1. Canard *et al.* (2012) built a species-based network from neutrally simulated interactions between individuals using a similar approach. In contrast, more sophisticated models need to be built when shifting to a finer level of organization. Indeed, knowing that two genera interact does not imply that all of their pairwise species combinations can also interact. One could, for example, build a finer-scale network by generating probabilities of species interactions by randomly sampling them from a beta distribution parametrized by the broader-scale network.

Ideally, the biological interpretation of probabilistic interactions should not differ across a network even if it has heterogenous levels of organization, i.e. if different nodes are represented at different taxonomic scales (e.g., a network composed of species and trophic species). This is frequent in ecological networks where taxonomic resolution is typically low (Hemprich-Bennett *et al.* (2021), Vázquez *et al.* (2022)). Broader-scale interactions should be based on probabilities of interactions between individuals, either at the local or regional scale. For example, in local individual-based food webs, the probability that two individuals interact represents the degree of belief that one individual will actually consume the other. Similarly, in local species-based food webs, the probability that two species interact represents the degree of belief that at least one individual from the predator species consumes at least another individual from the prey species. Moreover, in local clade-based food webs,

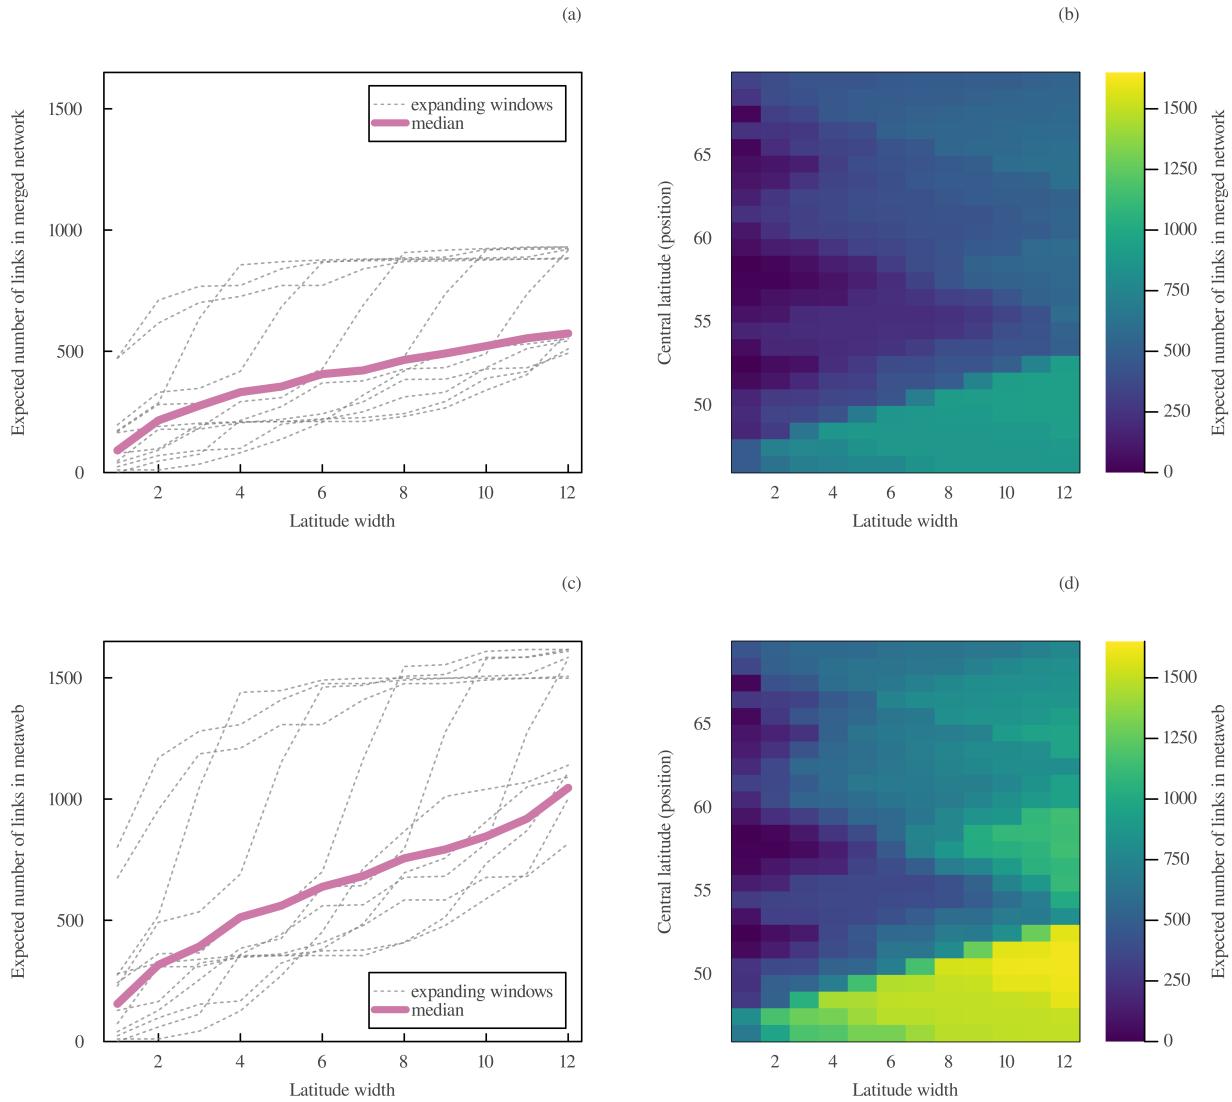

276 the probability that two clades interact represents the degree of belief that at least two species from these clades
277 interact with each other or, equivalently, that at least two individuals from these clades interact with each other.
278 Fundamentally, the taxonomic scaling of interactions is an aggregation of interactions between individuals into
279 larger groups, which could be more or less homogeneous depending on the organisms and the study system.
280 This type of scaling is analogous to the spatial and temporal scaling of interactions to the extent that they
281 represent different ways to aggregate individuals into broader groups, either spatially, temporally, or
282 taxonomically.

283 **Spatial and temporal scaling of interactions**

284 The study of network-area relationships (NARs) and interaction accumulation curves (IACs) are important
285 realms of research in network ecology. Firstly, NARs describe the scaling of network properties (such as
286 modularity and trophic chain lengths) with spatial scale (e.g., Wood *et al.* (2015), Galiana *et al.* (2018)). The
287 variation of network structure across spatial scales can be the result of the scaling of species richness
288 (species-area relationships, SARs) and the number of interactions (Brose *et al.* (2004)) with the area sampled,
289 but can also be due to ecological processes (e.g., spatial variability in community composition and extinction
290 and colonization events) occurring at different scales (Galiana *et al.* (2018)). Secondly, IACs describe the
291 scaling of the number of interactions observed with sampling effort (Jordano (2016)), which can impact many
292 measures of network structure such as connectance (McLeod *et al.* (2021)). Beyond sampling effort, the
293 temporal scaling of interactions describes how network structure changes with the duration of the network
294 (Poisot *et al.* (2012)) given that different interactions are occurring through time. Because probabilistic local
295 networks can assess the spatiotemporal variability of interactions (eq. 2), they are useful tools to develop and
296 test different equations of the scaling of network structure with space and time.

297 Metawebs and local networks intrinsically differ in their relationship to spatial and temporal scales. On one
298 hand, because probabilistic metawebs are context-independent, potential interactions do not scale with space
299 and time since they depend solely on the biological capacity of the two taxa to interact, regardless of any
300 particular environmental conditions. This suggests that the probability that two taxa can potentially interact
301 should theoretically be the same in all metawebs in which they are present, provided that the data and methods
302 used to estimate them are the same. As a result, if a potential network M_1 is subsampled from a regional
303 metaweb M_0 to represent the potential interactions between a subset of taxa found in a smaller region, their
304 probabilities of interaction should be identical regardless of scale, i.e. $P_{M_1}(i \rightarrow j) = P_{M_0}(i \rightarrow j)$. On the other

hand, local ecological networks scale both spatially and temporally since interactions have more opportunities to be realized and observed in a larger area and duration (e.g., more individuals, more trait variations, more chance of an encounter, McLeod *et al.* (2020)). For example, if a local probabilistic network N_1 of area A_1 is obtained from a larger network N_0 of area A_0 , with A_1 being completely nested within A_0 , interaction probabilities should be smaller in the smaller network, i.e. $P_{N_1}(i \rightarrow j | A_1 < A_0) \leq P_{N_0}(i \rightarrow j | A_0)$. However, if A_1 and A_0 are disjoint, interaction probabilities could be incidentally higher in the smaller area depending on their environmental and biological conditions. Similarly, interaction probabilities should be smaller in networks of shorter durations if time intervals are nested. Statistical models, such as network-area relationships and interaction accumulation curves, can be used to generate estimates of local probabilities of interactions across spatial and temporal scales.

315 **Box 1: A spatiotemporally explicit model of interactions**

316 Predicting local networks across time and space is an important goal of network ecology (Strydom *et al.*
317 (2021)). Indeed, in a context of scarcity of interaction data (Jordano (2016)), ecologists must rely on predictive
318 models to reconstruct networks at fine spatial and temporal scales. For example, local ecological networks
319 could be reconstructed using real-time biomonitoring data and adequate numerical models (Bohan *et al.*
320 (2017)), which could pave the way for fine-scale studies of ecosystem functioning and dynamics. Besides
321 predictive models, statistical models can also be built to describe parameters of interest, such as probabilities of
322 interactions. In that case, parameter values provide valuable ecological information in their own rights.
323 Different types of models (e.g., Bayesian and machine learning models) of ecological interactions have been
324 built for predictive and descriptive purposes (Strydom *et al.* (2021)). Representing interactions probabilistically
325 reflects the uncertainty of these models, which is usually represented in terms of probability distributions. Here
326 we show how to build a simple generative mechanistic model of probabilistic interactions that takes into account
327 their inherent spatiotemporal variability, i.e. a spatiotemporally-explicit model. Our model is not suitable for
328 potential interactions, which are scale-independent. Rather, it could prove useful for predicting local
329 interactions across time and space by generating new interaction data after parameter inference.

330 As stated by eq. 1, the probability that two taxa i and j interact at a given location (x, y) is given by the product
331 of their probability of interaction given co-occurrence and their probability of co-occurrence. First, their
332 probability of co-occurrence is given by their respective probabilities of occurrence $P_i(x, y)$ and $P_j(x, y)$ and the
333 strength of association γ between their occurrence and co-occurrence (Cazelles *et al.* (2016)):

$$P_{i,j}(x, y) = P_i(x, y)P_j(x, y)\gamma. \quad (5)$$

334 When $\gamma > 1$, the geographic distributions of both taxa are positively associated, which implies that the
335 occurrence of one taxon increases the probability of occurrence of the other. In empirical networks, $\gamma > 1$ for
336 most species pairs (Catchen *et al.* (2023)). The co-occurrence of both taxa is the result of a Bernoulli trial

$$C \sim \text{Bernoulli}(P_{i,j}(x, y)). \quad (6)$$

337 Second, the probability of interaction given co-occurrence can be made temporally explicit by modeling it as a
338 Poisson process with rate λ . This parameter corresponds to the expected frequency of interaction between both

339 taxa in a given time period and its value can be estimated using prior data on interaction strengths, if available.
 340 Specifically, the probability that two co-occurring taxa interact during a time period t_0 is:

$$P_N(i \rightarrow j|C = 1) = 1 - e^{-\lambda t_0}, \quad (7)$$

341 which approaches 1 when $t_0 \rightarrow \infty$.

342 The realization of the interaction between i and j is the result of a Bernoulli trial with probability $P_N(i \rightarrow j)$. A
 343 Bayesian inference model can thus be built from the previous equations to estimate the value of the λ parameter
 344 and generate new interaction data:

$$I \sim \text{Bernoulli}(P_N(i \rightarrow j)) \quad (8)$$

345

$$P_N(i \rightarrow j) = P_i(x, y)P_j(x, y)\gamma(1 - e^{-\lambda t_0}) \quad (9)$$

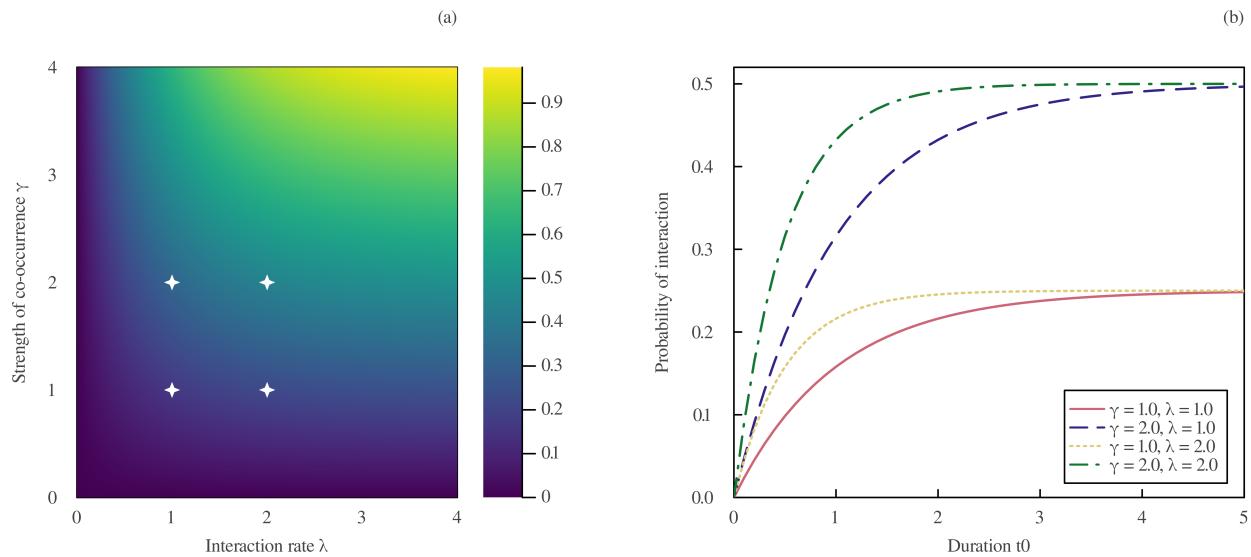

346

$$\gamma \sim \text{Gamma}(2, 0.5) \quad (10)$$

347

$$\lambda \sim \text{Exponential}(2) \quad (11)$$

348 This simple model can be customized in many ways, e.g. by linking λ with given environmental variables or by
 349 explicitly modeling observation errors (i.e., the probability of false negatives and false positives).

350

351 **Sampling binary networks**

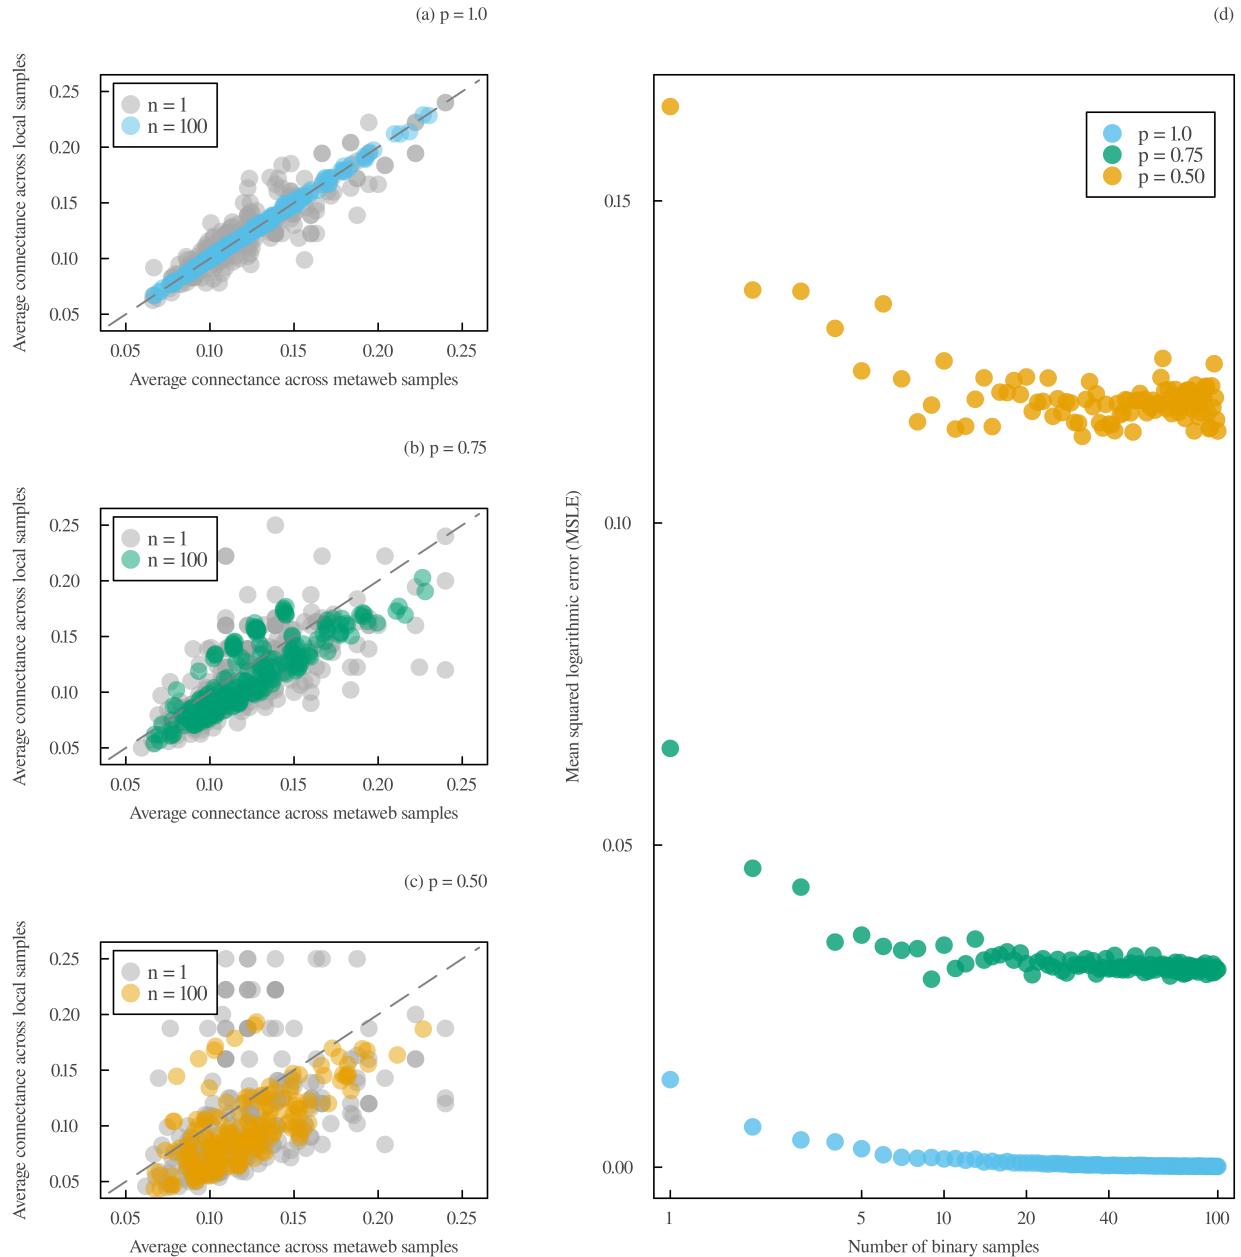

352 Probabilistic networks can be used to predict binary interactions through random draws. This can be useful
353 when analyzing the structure of a probabilistic network when analytical probabilistic measures are lacking. A
354 binary network can be generated from independent Bernoulli trials for each interaction. The distribution of a
355 network's property can then be obtained after measuring the structure of all randomly generated networks
356 (Poisot *et al.* (2016)). Doing so allows us to represent the variability of network structure, although possibly
357 with biases when connectance is low (Poisot & Gravel (2014), Chagnon (2015)). When binary networks are
358 generated under a null model, this method can be used for null hypothesis significance testing, in which case the
359 observed measure is compared to a null distribution (e.g., Bascompte *et al.* (2003)). Furthermore, randomly
360 generating binary networks across space and time can help us visualize the spatiotemporal variability of
361 network structure and test ecological hypotheses on interactions across large spatial and temporal scales.

362 There are at least two different approaches when sampling binary networks from probabilistic webs across
363 space, e.g. if we want to predict a binary network for each of $n \times n$ grid cells. The first approach is to conduct a
364 single Bernoulli trial for each pair of taxa found in the region of interest based on their regional probability of
365 interaction. As a result, each pair of taxa that are predicted to interact in the regional network realization will
366 interact in all of the n^2 networks in which they co-occur. This sampling technique is best used with potential
367 interactions that have no spatial variation. The second approach is to independently sample each of the n^2
368 networks. In practice, this can be done by generating a different probabilistic network for each grid cell.
369 Depending on how they were obtained, these networks can differ in their taxa composition (nodes) and/or
370 interaction probabilities (edges). Then, binary networks can be independently sampled for each grid cell.
371 Because this method generates spatial variation in binary interactions, it is best used with local interactions.

372 The choice of sampling approach has an impact on the selection of grid cell size. In the first approach,
373 interactions will be the same regardless of cell size because interactions are sampled only once from the
374 regional network. However, in the second approach, local interaction probabilities depend on the network area.
375 For example, let N_1 and N_2 be networks of area $\frac{1}{2}A_0$ nested within A_0 and disjoint from each other, i.e. two
376 contiguous cells that form N_0 . If N_1 and N_2 are independent (which is rarely the case in reality because of
377 spatial auto-correlation), the probability that two taxa i and j interact in N_0 is given by:

$$P_{N_0}(i \rightarrow j) = 1 - (1 - P_{N_1}(i \rightarrow j)) \times (1 - P_{N_2}(i \rightarrow j)). \quad (12)$$

378 Because of its larger area, the probability that the two taxa interact in N_0 is higher than in N_1 and N_2 . When
 379 sampling binary interactions from local networks, it is thus important to sample at the same spatial scale as the
 380 one for which probabilities were estimated. Otherwise, interaction probabilities must be adjusted to correspond
 381 to the targeted cell size and avoid systematic biases in prediction.

382

383 **Prediction of local networks from metawebs**

384 Metawebs are an important source of ecological information that can be leveraged for predicting local networks.
385 Indeed, binary local networks can be reconstructed by selecting a subset of both taxa and interactions from the
386 metaweb (Dunne (2006)). This implies that there are always more interactions in a metaweb compared to its
387 corresponding local networks. In practice, because a community's composition is arguably easier to sample or
388 predict than its interactions, the list of taxa to select can be known empirically or obtained using range maps or
389 species distribution models. The challenge is rather to choose which interactions to select from the metaweb,
390 which could require more sophisticated statistical models and ecological knowledge. Because the structure of
391 local networks is constrained by the one of the metaweb (Saravia *et al.* (2022)), inferring their structure from
392 the metaweb before predicting local pairwise interactions could prove promising (Strydom *et al.* (2021)).

393 When building probabilistic local networks from a probabilistic metaweb, interaction probabilities decrease.
394 This is because two taxa must first have the capacity to interact (i.e., $M_{i,j}^* = 1$ in the binary metaweb M^*) before
395 interacting locally:

$$P_N(i \rightarrow j) = P_M(i \rightarrow j) \times P_N(i \rightarrow j | M_{i,j}^* = 1).$$

396 Therefore, inferring local networks from their metaweb keeping the same values of interaction probability
397 would generate systematic biases in the prediction. In that case, these networks would instead represent
398 smaller-scale metawebs of potential interactions, which could be misinterpreted as local interactions. As
399 suggested by McLeod *et al.* (2021), even though metawebs do not capture the spatiotemporal variability of
400 interactions, they set the upper limit of local interactions. In other words, the probability that two taxa interact at
401 a given location and time is always lower or equal to the probability of their potential interaction:

$$P_N(i \rightarrow j | A, t, C, \Omega) \leq P_M(i \rightarrow j). \quad (13)$$

402 Moreover, the probability that two taxa have the biological capacity to interact must be higher than the
403 probability that they will ever interact because they might never co-occur or encounter locally. More precisely,
404 the accumulated probability of realized interactions across all spatial, temporal, and environmental conditions
405 must be lower than the probability of potential interaction, i.e.

$$\int_{\Omega} \int_A \int_t P_N(i \rightarrow j | A, t, \Omega) dt dA d\Omega \leq P_M(i \rightarrow j). \quad (14)$$

406 Conclusion

407 In this contribution, we underlined the importance of network metadata for adequately interpreting and
 408 manipulating probabilistic interaction data. Indeed, the mathematical representation of probabilities and their
 409 statistical properties depend on the type of interactions (local or potential) and the conditions in which they
 410 were estimated. We showed that probabilistic local networks and metawebs differ in their relationship to spatial
 411 and temporal scales, with potential interactions being scale-independent. In contrast, local interactions are
 412 measured in a specific context (e.g., in a given area, time, and biological and environmental conditions) and are
 413 conditional on taxa co-occurrence. These important conceptual differences bring to light the need to use
 414 probabilistic data with caution, for instance when generating binary network realizations across space and
 415 predicting local networks from metawebs. Clear metadata describing the type of interaction and the variables
 416 used in their estimation are required to ensure adequate data manipulation. Better data practices and rigorous
 417 foundations for probabilistic thinking in network ecology could enable more reliable assessments of the
 418 spatiotemporal variability and measurement uncertainty of biotic interactions.

419 Acknowledgment

420 We acknowledge that this study was conducted on land within the traditional unceded territory of the Saint
 421 Lawrence Iroquoian, Anishinabewaki, Mohawk, Huron-Wendat, and Omàmiwininiwak nations. This work was
 422 supported by the Institute for Data Valorisation (IVADO) and the Natural Sciences and Engineering Research
 423 Council of Canada (NSERC) Collaborative Research and Training Experience (CREATE) program, through the
 424 Computational Biodiversity Science and Services (BIOS²) program. A special thanks to all members of the
 425 Black Holes and Revelations working group (organized by BIOS²) for their insightful discussions and valuable
 426 feedback on this manuscript.
